Reconstructive Surgery of the gastrointestinal tract is the next great step in the further development of laparoscopic surgery. The largest field is colonic resection with restoration of the bowel continuity by anastomoses. It has been done in several centres, so far. The future will show whether it will become a routine procedure and for which indications it will be the appropriate method.

Indication to laparoscopic colonic resection is generally approved for all benign lesions (Table 1) and it is kept restricted to these in most German centers (Table 2). Many European (8,11) and American Surgeons (4,5,15,21) have, however, applied laparoscopic bowel resection also to colonic cancer (Table 3). Since the inferior mesenteric artery can be transected close to the aorta, after mobilising all adjacent lymphatic tissue towards the mesocolon segment to be resected, there should not remain severe doubts to the tumor eradication from the oncologic view (9).

All types of colonic resections have been performed meanwhile, even total colectomies (Table 4). All but sigmoid resection and rectal excision require an additional, mostly small laparotomy incision for withdrawal of the resected specimen; they are performed laparoscopically assisted. The laparotomy incision is generally used to perform an open anastomosis.

A thorough bowel preparation is required the day before surgery by means of orthograde bowel lavage with 4–5 L Golytely solution or 6–8 L Ringer's lactate.

Operative Technique

Exemplary, sigmoid resection is described. The patient is placed in Trendelenburg position under general anesthesia. After insertion of the Verres needle a pneumoperitoneum is instituted with CO₂ up to an intrabdominal pressure of 14 mmHg. The optic trocar is inserted below the navel (Fig. 1). The further trocars are placed under endovisional control. In obese patients we use a higher insertion for the optic trocar (Fig.2). The position of the trocars may be varied according to anatomy. The instrumentation (Fig.3) through the trocars is listed in Table 5. The operating table is turned head-down and to the right about 20 degree each. The surgeon works from the patient's right side.

Phase I is the dissection of the anatomical structures and resection of the specimen. The instrumentation through the above mentioned trocar sites is applied, with great variability. Therefore we generally use 10/11 mm trocars that allow passing the optic and almost any instrument (except for linear staplers) through any trocar. The multiple methods of surgical dissection are shown in Table 6. The sigmoid colon is lifted up and skeletonized over a short segment (Fig.4). For dissection we use the Endo-sissors with monopolar coagulation rather than an electrosurgical hook. Small vessels can be coagulated with the closed-sissors and than be cut. Vessels of bigger size are cut between clips (Fig.5). In case of a fatty mesocolon we apply ultrasound dissection with a Sonocut (Soring Company, Quickborn/Hamburg) which allows skeletonizing of vascular structures and clonic wall without bleeding (Fig.6); once they are clearly isolated they can be further handled easily. Ultrasound dissection necessitates a 10 mm trocar. It should not be applied in the mesocolon pedicle in the possible presence of metastatic lymph nodes.

With a linear stapler bigger bites of the mesocolon can be divided (Fig.7). Since its opening is limited, it might be not applicable in fatty mesocolon. Here again, ultrasound dissection is helpful. Finally, the colon is transsected (Fig.8) in the skeletonized segment by means of a linear stapler (Endo-GIA, USSC-Autosuture Company).

Table 4. The different types of colonic resection procedures. Not all types are listed up; thus the sum of the listed procedures differs from the total number given in table 3. Only sigmoid resection and rectal excision allow a purely laparoscopic performance, with the specimen withdrawn via the transanal way or the perineal wound respectively. All higher resections require an additional small laparotomy incision, through which the specimen can be withdrawn.

Intraoperative coloscopy is recommended in order to define the level of resection and to ascertain that the lesion be within the specimen (5,11). For easier dissection of the mesocolon the bowel may be lifted up by loops in the resectional planes. As a further technical aid an elevator for the abdominal wall may be inserted which saves gas pressure.

Phase II concerns removal of specimen (Table 7). In the purely laparoscopic procedures the resected colon segment is withdrawn through the rectum para-nally by means of a long curved forceps (Fig.9). This can only be done if the specimen is fairly small. The extraction may be eased by a slim bag, i.e. the slim tube of the camera cable, and a lubricant. We succeeded with this way of extraction in all but two patients. In these two with diverticulitis we had to do a mini-laparotomy to remove the specimen. Morcellation of a benign specimen within an impervious bag may be considered since in case of diverticulitis histology is of minor importance (5,11). For small specimens a coloscopically introduced sling (Fig.10) is feasible (5). For extraction through the abdominal wall a 33 mm (thirty three millimeter) trocar (Fig.11) is supplied (Ethicon), which is unrenouncable for higher colonic lesions, i.e. in the right colon.

The great majority of surgeons prefer the laparoscopic assisted colonic resection. This method outnumber the purely laparoscopic procedures by far. A small laparotomy incision at the point of resection serves for extracting the specimen as well as for open anastomosis. The extraction is to be accomplished by means of a bag in order to avoid spilling of bowel contents and especially tumor cell seeding. Metastases in the abdominal wound were reported by Wexner on the Endoscopic Surgery Meeting at Koln in June 1993.

Phase III is the reconstruction. The techniques of anastomoses are multiple (Table 8). An end-to-end colonic anastomosis is to be instituted. In laparoscopic assisted procedures this is performed through the mini-laparotomy or by extracting the oral and aboral colonic stump outwards the abdomen. The anastomosis may be done by manual suturing as well as by circular stapler, the latter being possible only within reach of the transanally introduced stapler (25-30 cm).
Figure 2. The abdominal ports are placed in a 63 year old obese patient for sigmoid resection. 10/11 mm trocars are used. The optic trocar is placed upwards and right of the navel. The trocars are fixed by sutures.

The same is true for laparoscopically performed anastomoses. This is a difficult maneuver. Perfect coordination of surgeon, assistant, and camera holder is required to introduce the head of the stapler device into the oral colonic stump. The head may be disconnected from the corpus for this purpose, to be reconnected later. The fixation of the resectional borders on the axis of the stapler device (Fig.12) is accomplished by a loop (5) or by manually applied (Fig.13) purse string suture (1,6). Köckerling (9) introduced a purse string suture clamp (Ethicon) which eases the performance of the purse string suture (Fig.3). After the colonic ends are well fixed on the axis, the stapler device...

Figure 8. The colon is transected by a linear stapler. The first transsectional bite has already been done. The linear stapler (Endo-GIA, 30 mm cut length, USSC-Autosuture Company) is now positioned for the second bite.
Table 7. The specimen removal is either done by a long curved forceps through the rectal stump per anum (it may be done with a slim specimen bag) or by means of a coloscopically placed loop. A large trocar makes removal possible through the abdominal wall. Or, finally, a mini-laparotomy is applied.

**Specimen Removal**

I. transluminal  
- curved forceps per anum  
- coloscopically placed loop  
- specimen bag

II. large trocar of 33 mm diameter

III. through mini-laparotomy  
- direct extraction  
- within specimen bag

Figure 9. The distal sigmoid stump is held open by Endo-forceps (left) and Babcock clamp (right). On the transanal way long curved forceps was brought in, which is now opened to grasp the specimen for extraction.

Figure 10. Small resected segments of the colon may be extracted transanally by means of a coloscopically placed sling (from Franklin (5)).

vice is shot off and gently removed. The resected tissue rings are checked for completeness.

We have mostly used the triple staple technique (Fig.14). Instead of using a purse string suture, the colonic ends are closed by linear staplers after the disconnected stapler-head has been introduced into the oral stump (Fig.15). Through small incisions the central pins of the head-part and the basic-axis are brought out. The parts of the stapler device are reconnected and approximated, before the mechanism is shot off. The linear staple lines of the oral and aboral stump must not lie on each other but rather have an angle of 90 degree.

Any stapler anastomosis has to be checked for leakage by transanally filling with water. In case of spillage sutures are required. Thus, the surgeon is requested to be able doing laparoscopic sutures and knots.

Figure 11. The 33 mm extraction trocar (Ethicon) is inserted through the abdominal wall. The large calibre allows extraction of the colonic resection specimen.

Table 8. A. Open technique through mini-laparotomy either by manual suturing or by circular stapler. B. Intraabdominal laparoscopic stapler technique. C. Intraabdominal laparoscopically hand sewn anastomosis.

**Technique of anastomosis**

A. open — manual suturing  
- circular stapler  
through small laparotomy incision  
- laparoscopic assisted

B. stapler technique  
- Roder loop  
- purse string suture  
- manually placed  
- applied with special clamp  
- triple staple technique

C. laparoscopic manual suture  
- interrupted; single knots  
- continuous suture (?)
With adequate training, it is possible to do laparoscopic sutures and knots intraabdominally. We have performed manual suturing of a colotomy and realized a colonic anastomosis with interrupted sutures (Fig.16) on the laparoscopic way (Fig.17). This may be the method in future. Continuous suturing for laparoscopic anastomoses has not been applied in man yet, only experimentally. It might be quicker and easier, but seems not to be as save.

Other forms of colonic resections as right and left hemicolectomy (4,6,5,8,10,15) can be performed in a similar manner. The abdominal ports must be placed in modified positions to allow access for mobilisation of the right or left colonic flexure under good visualisation. The operating table will be turned to have the
The central axis of the basic part is passed through the opening. The axis pin of the head part, which was placed in the oral stump, is introduced into the central axis.

Figure 14. C. Head and basic part of the Premium CEEA device have been connected and are being adjusted.

The point of dissection upwards. Subtotal colectomy has been performed (22).

In abdominoperineal rectal excision the mesocolon pedicle with division of the inferior mesenteric artery (9) is mobilized, the Sigmoid colon is transected and the rectal mobilisation from-out the sacral cavity and in the ventral space of Denovillier is accomplished laparoscopically. Then, as next step, the pelvic peritoneum has to be reconstructed by continuous suture and the oral sigmoid stump is pulled out through a small abdominal incision (which may be a dilated trocar insertion site) for colostomy. Only there after, when collapse of the pneumoperitoneum does not interfere with the laparoscopic procedure any more, rectal excision is performed from the perineal way. The presacral cavity is drained by silicone tubes; the perineal wound is closed primarily.

RESULTS AND DISCUSSION

The duration of the laparoscopic procedure is taken as one of the criteria of feasability. Initially, 5-6 hours are usual (5). But operation time is quickly shortened with the experience of the team to around 3 hours (4,5,8). Even the laparoscopically hand-sewn anastomosis (Fig.18) is possible to be accomplished within one hour, although our first one took 2 hours and a half.

The triple staple technique is quicker, in case none technical problems occur. And this was the predominant method that we have used in the past (Table 9). Small problems of getting the stapler device set in place may be extremely time consuming in a laparoscopic procedure. They may even necessitate conversion if the colonic wall is torn over the edge of the stapler head. A critical point of this anastomosis seems to be the crossing of the linear and the circular staple line. This is the one point where primary leakage or later Insufficiency is more likely to occur. In one case we found a primary leakage here which was closed by two sutures with 3-0 absorbable material on the laparoscopic way.

The end parts of the linear stapler lines, outwards the circular anastomosis, result in dog-ears. This is of no functional Importance. In colon contrast enemas these can hardly be seen. The coloscoplc anastomosis control showed minor bulging only (Fig.19).

Intraoperative complications render further criteria for the feasability of the laparoscopic procedure. There are technical complications that do no harm to the pa-
Figure 15. Triple staple technique, intraoperative application. Step A-D like figure 14. The linear staple line is crossed by the circular staple line. This is point of risk (leakage). The edge of the foregoing resection line by linear stapler is forming a dog ear (D right), which is however of no functional importance.

Figure 16.4. With the endoscopic needle driver (right) a 3-0 suture is placed for a manually sewn anastomosis, whilst the flamingo tie and tissue holder (left) withholds the colonic wall. The seromuscular suture is tied manually by means of the above instruments (Storz Company, Tuttingen/Germany) in the technique described by Szabo (20).

Clinical complications of minor importance to the patient are transient problems like subcutaneous emphysema or hypercapnia with $\text{PCO}_2$ above 60 mmHg. Blood loss may be minor for the patient but severely interfere with the laparoscopic procedure. Spilling of bowel contents into the abdominal cavity may occur once the bowel is opened; it should be prevented by coloscopically sucking before...

Postoperatively the clinical observation shows the patients well mobile, well breathing, and with almost no pain, already on the day after surgery. This is true also for patients that had operations of many hours duration. Usually, patients also have audible bowel activity already on the first postoperative day and bowel movements 2-3 days earlier than after open procedures. This is also true for laparoscopic-assisted operations. Evidently, it is the less traumatising of the bowel by the laparoscopic procedure that brings this benefit for the patient. The additional small laparotomy incision in laparoscopic-assisted procedures does hardly reduce this benefit. After abdomino-perineal rectal excision that we have performed laparoscopically in a 90-year-old female, she was well up already on the evening of the operating day, and she recovered quickly within 2 days to her previous activities. Bowel movement started on day 2 postoperatively over the colostomy in the left lower quadrant.

Figure 19. Coloscopy view of the staple anastomosis (Fig. 14) 6 weeks operatively. Only a minor bulging (right) is recognized at the position of the dog ear. Otherwise the anastomosis can hardly be visualized.
