Clinical Significance of Ki-67 Proliferation Index and p53 Gene Expression in the Evaluation of Hormone Profiles, Invasiveness and Pre- and Post-operative Assessment of Pituitary Macroadenomas

Ki-67 Proliferasyon İndeksi ve p53 Gen Ekspresyonunun Hipofiz Makroadenomalarının Hormon Profilleri, İnvazyon Dereceleri ve Operasyon Öncesi ve Sonrası Değerlendirilmesindeki Klinik Önemi

ABSTRACT Objective: The aim of this study was to investigate the clinical significance of Ki-67 proliferation index and p53 gene expression in the pre-operative and post-operative evaluation of pituitary macroadenomas. **Material and Methods:** We retrospectively evaluated 81 pituitary macroadenoma patients, where pre-operative, six-month and one-year follow-up post-operative dynamic contrast-enhanced magnetic resonance imaging examinations were present in our picture archiving and data system. All patients underwent surgical tumor removal and were pathologically diagnosed as having macroadenomas. **Results:** In Ki-67 positive macroadenoma cases, maximal tumor diameter was found significantly higher than in Ki-67 negative adenoma cases. When tumor invasiveness was compared based on Hardy's classification with the Ki-67 proliferation index values of macroadenomas, no statistically significant correlation was found between tumor invasiveness and Ki-67 values. We can state that there is a strong correlation between Ki-67 positiveness and increase in residual tumor dimensions. In p53 negative and positive macroadenoma cases, there was no significant correlation between p53 gene expression and maximal tumor diameter. When we compared the tumor invasiveness was compared based on Hardy's classification with the p53 gene expression of macroadenomas, no statistically significant correlation was found between tumor invasiveness and p53 values. We can say that there is a strong correlation between p53 gene expression positiveness and increase in residual tumor dimensions. **Conclusion:** Ki-67 proliferation index and p53 gene expression level determination of macroadenomas and their association with the hormone profiles, invasiveness, preoperative primary tumor and post-operative residual tumor dimension parameters can be combined in order to predict early tumor progression and patient prognosis.

Keywords: Immunohistochemistry; magnetic resonance imaging; pituitary adenoma; recurrence

ÖZET Amaç: Hipofiz makroadenomlarının, operasyon öncesi ve sonrası değerlendirilmesinde Ki-67 proliferasyon indeksi ve p53 gen ekspresyonunun klinik önemini araştırmak. **Gereç ve Yöntemler:** Çalışmamızda, operasyon öncesi ve sonrası 6. ay ve 1. yıl takip dinamik kontrastlı manyetik rezonans görüntüleme incelemeleri resim arşiv ve data sistemi içerisinde bulunan 81 hipofiz makroadenoma hastasını retrospektif olarak değerlendirdik. Tüm hastalarda, cerrahi olarak tümör çıkarıldı ve patolojik olarak makroadenoma tanısı konuldu. **Bulgular:** Ki-67 pozitif olan makroadenoma olgularında maksimal tümör boyutları, Ki-67 negatif olan adenoma olgularına göre belirgin derecede yüksek bulundu. Hardy'nin klasifikasyonuna göre tümör invazyonu ile makroadenomaların Ki-67 proliferasyon indeks değerleri karşılaştırıldığında, tümör invazyonu ile Ki-67 proliferasyon indeks değerleri arasında istatistiksel olarak anlamlı bir korelasyon saptanmadı. Ki-67 pozitifliği ile rezidüel tümör boyutlarındaki artış arasında güçlü bir korelasyon bulunduğunu söyleyebiliriz. Rezidüel tümör boyut artışı ile Hardy'nin klasifikasyonu arasında istatistiksel olarak önemli bir korelasyon mevcut değildir. p53 negatif ve pozitif makroadenoma olgularında, p53 gen ekspresyonu ile maksimal tümör boyutu arasında önemli bir korelasyon bulunmadı. Makroadenomaların, p53 gen ekspresyonu ile Hardy'nin klasifikasyonuna göre tümör invazyonu karşılaştırıldığında, p53 değerleri ile tümör invazyonu arasında istatistiksel olarak önemli bir korelasyon saptanmadı. Operasyon sonrası rezidüel tümör değerlendirilmesinde, p53 gen ekspresyon pozitifliği ile rezidüel tümör boyutları artışı arasında kuvvetli bir korelasyon bulunduğunu söyleyebiliriz. **Sonuç:** Makroadenomaların Ki-67 proliferasyon indeksi ve p53 gen ekspresyon düzeylerinin saptanması ve bunların hormon profilleri, invazyon, operasyon öncesi primer tümör ve operasyon sonrası rezidüel tümör boyutu parametleri ile olan ilişkileri erken tümör progresyonunun ve hasta prognozunun tahmininde kombine olarak kullanılabilir.

Pituitary adenomas constitute about 10-15% of all intracranial tumors.[1] Although they are usually benign and have a tendency to slow growth, in some cases adenomas may present with signs of mass effect like visual loss, hypopituitarism and hormonal problems. In approximately one third of the cases, infiltration of the surrounding structures including the cavernous sinus can be seen and this can partly explain why relapsing might occur frequently even after total removal of the tumor tissue.[2,3] These tumors are usually huge in size and have an invasive nature, therefore complete surgical removal is almost impossible in most of the cases. Large tumor size, invasion and inadequate resection of the tumor are important risk factors in terms of progression or recurrence.[4] Some histologic predictors have been used to evaluate tumor progression or recurrence. Ki-67 is known as a nuclear antigen and its labeling index is regarded as a marker for normal and abnormal cellular proliferation (growh fraction). Immunohistochemical p53 gene expression has also been used as another histologic marker in daily practice. The aim of our study was to investigate the utility of these two histologic markers in the prediction of clinical and radiologic findings of macroadenomas. These include hormone profiles, invasiveness, preoperative primary and postoperative residual tumor dimensions. We sought a correlation between these two histologic markers through obtained clinical and radiological findings.

MATERIAL AND METHODS

PATIENT SELECTION

This study was approved by our Instutitional Research Ethics Committee and informed consents were obtained from all of the patients (Ethics Committee Approval: Ethics Committee of Şişli Hamidiye Etfal Training and Research Hospital, decision no: 1429, date: 25.2.2020). The study was carried out according to Helsinki Declaration principles. Beetween March 2015 and April 2019, retrospective evaluation of 81 pituitary macroadenomas was performed where preoperative, six-month and one-year follow-up postoperative dynamic contrast-enhanced magnetic resonance imaging (MRI) examinations were available in our picture archiving and data system. In all patients, the tumors were removed surgically and pathology diagnoses were consistent with macroadenoma. Patient cohort was of 39 males (48.2%) and 42 females (51.8%). Their mean age was 45.6±12.55 years. Mean tumor diameter was calculated as 27.1±10.8 mm (12-62 mm). They were classified as 17 null cell adenoma, 16 pluriform adenoma, 16 adrenocorticotrop hormone (ACTH)-releasing adenoma, 19 growth hormone (GH)-releasing adenoma and 13 gonadotropine-releasing adenoma based on hormonal profiles.

MAGNETIC RESONANCE IMAGING ANALYSIS

MR examination was performed by using a 12-channel phased-array head coil on a 1.5 tesla clinical scanner (Avanto- SQ Engine, Siemens, Erlangen, Germany). MRI parameters were as follows: First, non-contrast Turbo spin echo (TSE) sagittal T2 weighted [time to repeat (TR): 2700 msec, time to echo (TE): 96 msec, slice thickness 3 mm, field of view (FOV): 180x180 mm, nex: 2, matrix: 256x320], TSE coronal T2 weighted (TR: 2630 msec, TE: 96 msec, slice thickness 3 mm, FOV: 180x180 mm, nex: 2, matrix: 224x320), TSE sagittal T1 weighted (TR: 500 msec, TE: 17 msec, slice thickness 3 mm, FOV: 180x180 mm, nex: 2, matrix: 205x256), TSE coronal T1 weighted (TR: 500 msec, TE: 17 msec, slice thickness 3 mm, FOV: 180x180 mm, nex: 2, matrix: 205x256) and axial TSE T1 weighted (TR: 410 msec, TE: 8 msec, slice thickness 5 mm, FOV: 230x230 mm, nex: 2, matrix: 205x256) images were obtained. Then, following 0.1 mmol/kg iv gadolinium administration, sagittal and dynamic coronal plane TSE T1 weighted (TR: 300 msec, TE: 12 msec, slice thickness 3 mm, FOV: 180x180 mm, nex: 2, matrix: 205x256) images were also provided. All patients had pre-operative, six-month and one-year follow-up post-operative dynamic contrast-enhanced MRI examinations.

The images were interpreted by two experienced neuroradiologists by consensus who were blinded to the patients' pathology results. In all cases, maximal primary tumor and residual tumor diameters on pre-operative and post-operative MRI scans were calculated, respectively. Hardy's classification system was used to evaluate invasiveness of macroadenomas and categorized into five types: A) tumor bulging into the chiasmatic cistern, B) tumor reaching the anterior third

ventricle, C) huge suprasellar extension filling the third ventricle entirely, D) parasellar extension into the frontal, temporal, or posterior fossa, E) lateral expansion towards the cavernous sinus.[5]

PATHOLOGIC EVALUATION

Pathology and immunohistochemistry (IHC): The surgical specimens used in this study were obtained from neurosurgery clinics. Formalin-fixed and paraffin-embedded sections of 4 µm from samples were used for IHC staining. Paraffin-embedded tissue Ki-67 and p53 re-evaluation was scored by a specialized pathologist. The biological markers of proteins were analysed based on the immunohistochemical analysis protocol in paraffin sections by using the staining procedure. Leica bond system dewaxed paraffin by using leica reagent. Leia cell conditioning solution (pH 8.4, -100 °C, 60 min) was applied in order to restore antigenic epitopes. Those sections were incubated by using monoclonal antibodies during 32 min at 37 °C and identified with leica DAB detection kit. At the end of IHC reaction, these sections were contrasted with hematoxylin solution, then coloured with the reagent of an aqueous solution of buffered lithium carbonate, and finally covered with glass slides. All IHC results were independently reviewed by the neuropathologist who was blinded to the clinical data. They were expressed in the nucleus with the color of the red.

STATISTICAL ANALYSIS

For statistical analysis, the software named SSPS 15.0 for Windows was applied. Descriptive statistics were determined as follows: For categorical variables, number and percentage, for numerical variables mean, standard deviation, minimum, and maximum were used. The ones in groups were compared using the chi-square test. Since numerical variables showed a normal distribution pattern, the Student's t-test was used for comparison. The intersection value was analyzed using ROC curve analysis. Statistical significance level alpha was determined as $p<0.05$.

RESULTS

Our patient cohort's clinic, radiology and pathology features were summarized on Table 1. In this study, we considered Ki-67 proliferation index as positive at a 2-3% and above levels. Thus, 63 patients (77.8%) were found to be Ki-67 negative and 18 patients (22.2%) were positive. Regarding p53 gene expression, 76 patients (93.8%) were negative and only 5 patients (6.2%) were positive. In comparison of Ki-67 negative and positive macroadenoma cases in terms of tumor dimensions, maximal tumor diameter was found as 12-44 mm (mean diameter: 25.4±8.8 mm) and 13-62 mm (mean diameter: 32.9±15 mm) in Ki-67 negative and positive cases, respectively. Hence, in Ki-67 positive macroadenoma cases, maximal tumor diameter was found significantly higher than in

Ki-67 negative adenoma cases (p=0.009) (Picture 1, Figure 1). A receiver operating characteristic (ROC) curve analysis was carried out in order to predict Ki-67 positivity using maximal tumor diameter and a cutoff value of ≥26.5 mm yielded a 66.7% sensitivity and a 57.1% specificity (Figure 2). When we compared tumor invasiveness based on Hardy's classification with the Ki-67 proliferation index values of macroadenomas, there was no statistically significant correlation between tumor invasiveness and Ki-67 values (p=0.652) (Picture 2, Table 2). Regarding the hormone profiles of macroadenomas in correlation with Ki-67 values, we observed that in Ki-67 positive tumors, although the number of ACTH-releasing adenoma cases were significantly lower, go-

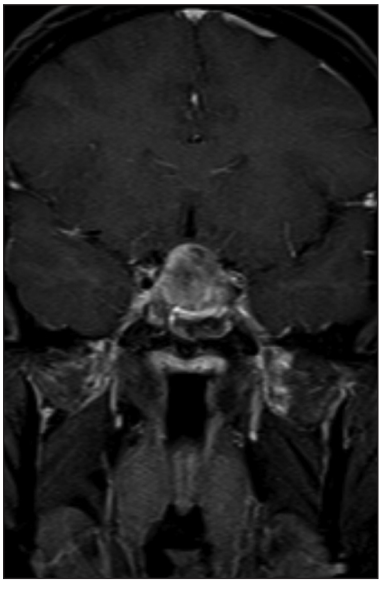
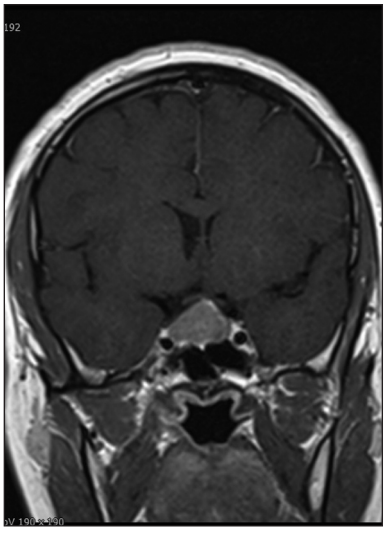
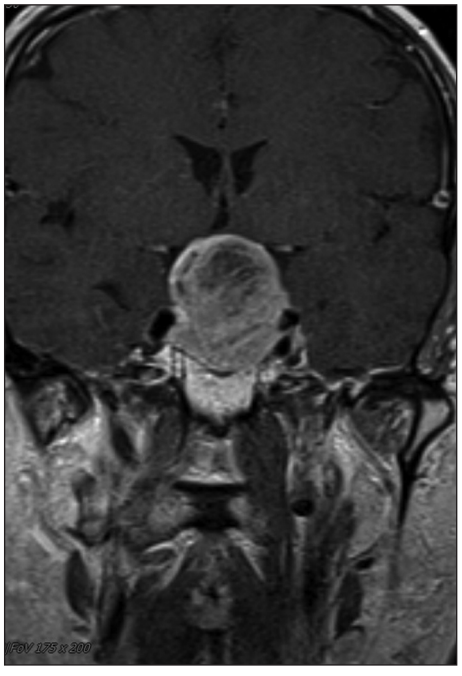
nadotropine-releasing adenoma cases were found significantly higher compared to Ki-67 negative macroadenoma cases (p=0.008) (Picture 3, Table 2, Figure 3). Post-operative residual tumor evaluation showed that in Ki-67 negative cases, in 60 out of the total 63 patients (95.2%), no increase in residual mass was detected, and in only 3 cases (4.8%) an increase in residual mass dimension was found. However, in Ki-67 positive macroadenoma cases, 12 out of 18 (66.7%) patients showed an increase in their residual tumor size and in only 6 cases (33.3%) there was no increase in residual tumor. These findings showed that there is a strong correlation between Ki-67 positiveness and an increase in residual tumor dimension



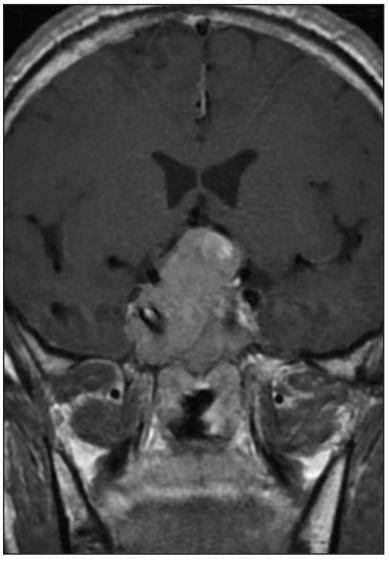
PICTURE 2a: Coronal T1 weighted contrast-enhanced magnetic resonance imaging (MRI) of a 46-year-old man. A Hardy's D suprasellar mass lesion is detected. Patient was Ki-67 negative.



PICTURE 2b: Coronal T1 weighted contrast-enhanced MRI of a 35-year-old woman. Another Hardy's D suprasellar mass lesion is present, but the patient is Ki-67 positive.



PICTURE 2c: Coronal T1 weighted contrast-enhanced MRI of a 43-year-old man. Hardy's E suprasellar mass lesion is present. Patient was Ki-67 negative.



PICTURE 2d: Coronal T1 weighted contrast-enhanced MRI of a 51-year-old man. Another Hardy's E suprasellar mass lesion is present, but the patient is Ki-67 positive.

(p=0.001) (Picture 4, Table 2, Figure 4). When we compared the residual tumor mass diameters with the pre-operative primary tumor, we observed that in increased residual tumor size cases, there was a strong correlation with pre-operative higher tumor dimension (Picture 5, Table 3) (p<0.001). On the other hand, there was no statistically significant correlation between residual tumor increase and Hardy's classification (p=0.253) (Table 3). In comparison of p53 negative and positive macroadenoma cases, maximal tumor diameter was found to be 12-56 mm (mean diameter: 26.6±10.3 mm) and 20-62 mm (mean diameter: 34.2±17.1 mm) in p53 negative and positive cases, respectively. In p53 negative and positive macroadenoma cases, there was no significant correlation between p53 gene expression and maximal tumor diameter (p=0.132). When we compared tumor invasiveness based on Hardy's classification with the p53 gene expression of macroadenomas, there was again no statistically significant correlation between tumor invasiveness and p53 values (p=1.000) (Table 4). Regarding the hormone profiles of p53 negative and p53 positive macroadenomas, we found no significant correlation between the p53 gene expression and the hormone profiles of macroadenomas (p=0.232) (Table 4). Post-operative residual tumor evaluation revealed that in p53 negative cases, in 64 cases from a total of 76 patients (84.2%) no residual mass was found, but in 12 cases (15.8%) there was an increase in residual mass dimension. However, in

TABLE 2: Comparison of Ki-67 positive and Ki-67 negative cases in terms of Hardy's classification, hormone profiles and post-op residual tumor increase.

	Ki-67

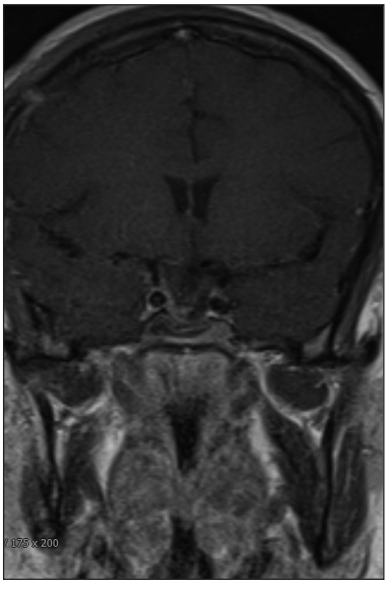
relation between the hormone profile of macroadenomas and increased residual tumor size (p=0.101) (Table 6).

DISCUSSION

Computed tomography (CT) and MRI are widely being used in the evaluation of pituitary macroadenomas. While MRI enables comprehensive delineation of the intrasellar and parasellar soft tissue structures with excellent contrast resolution, CT provides a detailed anatomical assessment of the sellar bony structures. Pituitary invasive macroadenomas have high recurrence rates. They are not considered to be malignant tumors and their biological behaviour is presumed to be between non-infiltrative adenomas and carcinomas. Radiological signs of tumor invasion

PICTURE 4c: Coronal T1 weighted contrast-enhanced MRI of a 45-year-old woman. An intrasellar mass lesion located in the right lobe of the gland is present. The patient was Ki 67 positive.



PICTURE 4d: Coronal T1 weighted post-operative six-month follow-up contrast-enhanced MRI of the same patient shows no residual mass.

should be considered with the presence of those findings: complete erosion of the clivus, tumor elongation inferiorly to the sphenoid sinus and tumor extension beyond to the lateral boundary of the cavernous carotid artery or complete encircling of the artery.

In order to predict tumor behaviour of macroadenomas, some histological markers have been used. In this regard, Ki-67 labeling index and p53 gene expression have been considered as useful histologic predictors in relevance to the progression or recurrence of macroadenomas. Ki-67 is regarded as a cell cycle specific nuclear antigen and can be easily recognised by various immunohistochemical methods like monoclonal antibody MIB-1.[6] It is typically expressed in proliferating cells during the G1, S, G2 and M phases of the cell cycle except G0 phase.[7] MIB-1 antibody can provide detection of Ki-67 in formalin-fixed and paraffin-embedded tissues. It provides knowledge about cellular proliferation rate or tumor growth fraction and hence can be used in the routine histologic evaluation of brain tumors including pituitary macroadenomas. But in pituitary macroadenomas Ki-67 labeling index levels have usually been found to be relatively low compared to other brain tumors.[8] A Ki-67 proliferation index level

of 2-3% and above was considered as positive in this study. p53 expression of the tumors can also be detected by using immunohistochemical methods. p53 gene product is a nuclear phosphoprotein whose immunohistochemical accumulation has been regarded as an unfavorable prognostic factor for a broad range of human tumors. It can also be used as a histologic predictor in the evaluation of tumor behaviour of macroadenoma cases. Although overall expression rate of p53 has been found to be low in many studies, its overexpression could correlate with progression or recurrence of macroadenomas. Thapar et al. in their study found that a Ki-67 labeling index cutoff value of 3% and higher had a 73% sensitivity and 97% specificity in the discrimination of noninvasive versus invasive macroadenoma cases.[9] Pizarro et al. measured Ki-67 antigen levels of 159 pituitary adenomas using MIB-1 monoclonal antibody test. They found that tumoral proliferative activity detected by the level of Ki-67 antigen is significantly higher in invasive adenomas compared to those of noninvasive ones.[1] Zhao et al. in a 57 clinically verified invasive pituitary adenoma cases found a significant association between Ki-67 labeling index and the invasiveness of the tumor. They concluded that Ki-67 labeling index detected by MIB-1 could be an important marker in the evaluation of potential invasiveness of pituitary adenomas.[10] Paek et al. investigated the correlation between Ki-67 labeling index with clinical and radiological characteristics of pituitary macroadenomas in 44 patients. They found that clinical findings such as visual field defect and recurrence were correlated with the high Ki-67 labeling index. But there was no statistically significant correlation between Ki-67 labeling index and sex, age, type of tumor, maximal tumor diameter, Hardy's clas-

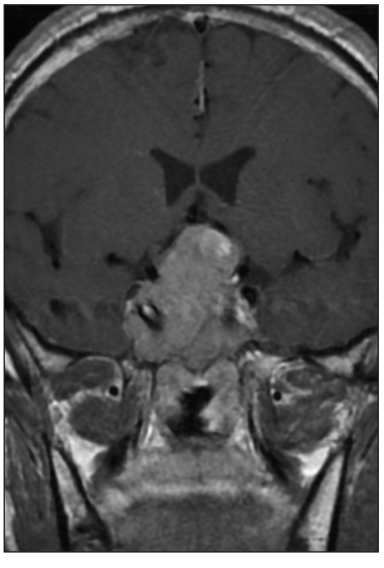
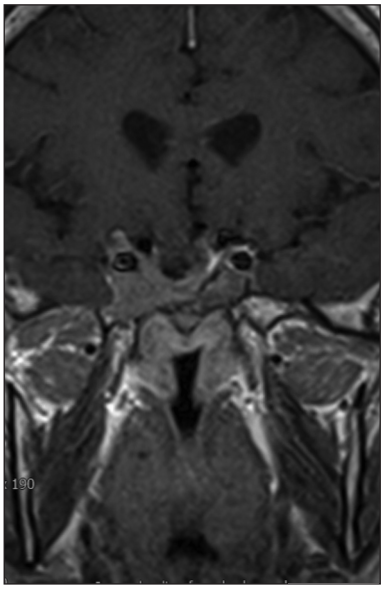
sification and invasiveness of tumor into the sphenoid sinus or cavernous sinus.[11] In our study, we evaluated tumor invasiveness according to Hardy's classification and compared these radiologic findings with the Ki-67 proliferation index values of macroadenomas. However, we did not find a statistically significant correlation between tumor invasiveness and Ki-67 values. The tumor size, indicated as the maximal diameter of the tumor on MRI and its relationship to the Ki-67 labeling index was investigated in some studies and there was no significant correlation.[11,12] In our study, maximal tumor diameter was found to be significantly higher in Ki-67 positive macroadenoma cases than those of Ki-67 negative ones. Jaffrain-Rea et al. assessed the proliferative index in a prospective series of 132 pituitary tumors and found that Ki-67 values showed escalation with increased tumor volume and invasiveness.[13]

Although there is a benign nature and slow growth rate in adenomas, their recurrence rate could be as high as 10% to 35%.[4] The most reasonable explanation for this situation might be inadequate removal of the tumor. Paek et al. in their patient cohort of a total 44 pituitary macroadenomas found that in 14 cases tumor recurrence occured. In this group, macrodenomas with recurrence had a significantly higher mean Ki-67 labeling index values (1.27%) than those of without recurrence (0.56%).[11]

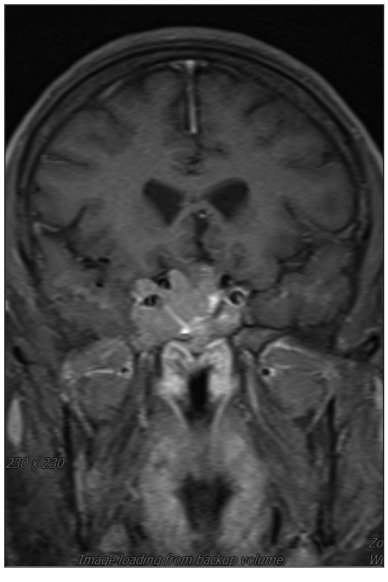
Filippella et al. in their study including 45 pituitary adenomas determined a cut off value of 2.9% for Ki-67 proliferation index and emphasized this value as the most reliable biologic marker in terms of predicting recurrence status of pituitary macroadenomas.[14] Shibuya et al. showed that recurrent pituitary adenomas exhibited higher Ki-67 labeling index val-



PICTURE 6a: Coronal T1 weighted contrast-enhanced magnetic resonance imaging (MRI) of a 51-year-old man. A huge intrasellar mass lesion extending to the third ventricular region and encasing both cavernous carotid arteries is present. The patient was p53 positive.



PICTURE 6b: Coronal T1 weighted post-operative six-month follow-up contrast-enhanced MRI of the same patient shows residual mass on the right.



PICTURE 6c: Coronal T1 weighted post-operative one-year follow-up contrast-enhanced MRI. There is an obvious increase in residual mass.

ues (3.6%) than those of primary adenomas (0.8%).[15] Ekramullah et al. in their study demonstrated significantly higher Ki-67 proliferation index values in the regrowing pituitary adenoma group compared to the cured adenoma patients (0.86% and 0.23%, respectively).[16] Contrary to these results, there are some studies in the literature which do not support a relationship with Ki-67 proliferation index and recurrence. Scheithauer et al. studied 176 pituitary tumors and did not find an association between the Ki-67 proliferation index and recurrence. They had only 7 patients with recurrence in a total of 78 cases whose Ki-67 proliferation index values were found to be more than 3%.[17] In our study, we found a strong association between Ki-67 positiveness and increase in residual tumor dimensions.

In the literature, there are studies that investigated whether the association could be between pituitary tumor Ki-67 labeling index levels with their hormone profiles. Thapar et al. showed significantly higher mean growth fraction levels in hormonally active pituitary adenomas (3.25%) compared to those of non-functioning adenomas (2.06%).[9] Wolfsberger et al. in their 150 functioning adenoma series found that silent ACTH-cell and prolactin-releasing adenomas had the highest, but null-cell adenomas and gonadotropinomas had the lowest proliferation index values.[18] On the other hand, Pizarro et al. in a 139 pituitary adenoma cases did not find a correlation between tumoral proliferative activity expressed by Ki-67 antigen and hormonal status of adenomas.[1]

In our study, we found that gonadotropine-releasing adenoma cases were significantly higher, whereas ACTH-releasing adenoma cases were significantly lower in Ki-67 labeling index positive adenoma cases. Besides, maximal diameter of ACTH-releasing adenomas was found to be significantly lower than those of null cell adenomas and pluriform adenomas. On the other hand, there was no statistically significant correlation between the hormone profiles and increased residual tumor size.

TABLE 6: Comparison of hormone profiles and post-operative residuel mass increase.

	Residual increase in size				
	Negative		Positive		
Hormone	n	%	n	%	p value
Null cell	14	82.4	3	17.6	0.101
Pluriform	13	81.3	3	18.8	
ACTH	16	100.0	0	0.0	
GH	15	78.9	4	21.1	
Gonadotrope	8	61.5	5	38.5	

ACTH: Adrenocorticotrop hormone; GH: Growth hormone.

Gejman et al. in their study indicated that a threshold value of 1.3% for the Ki-67 labeling index could be considered as a very suggestive indicator for post-operative tumor progression, but they did not find a significant association between p53 overexpression and tumor progression or recurrence.[19] Thapar et al. in their study consisting of 70 pituitary adenomas and 7 carcinomas demonstrated a highly significant correlation between p53 expression and biologic behaviour of pituitary tumors. They found immunopositivity for p53 in a total of 12 cases in their patient cohort in which all of them were either invasive adenoma or pituitary carcinoma cases. They concluded that p53 expression might have diagnostic utility in the prediction of aggressive tumor behaviour.[20] We also found a significant correlation between p53 gene expression positiveness and increase in residual tumor dimensions.

CONCLUSION

In conclusion, determination of Ki-67 proliferation index and p53 gene expression levels in macroadenomas and their relationship to the hormone profiles, invasiveness, preoperative primary tumor and postoperative residual tumor dimension parameters can be combined in the prediction of early tumor progression and patient prognosis. Thus, active surveliance and treatment protocols can be developed more specifically with these combined protocols and may be individualized for each patient. Further comprehensive studies are required to ratify our findings.

Source of Finance

During this study, no financial or spiritual support was received neither from any pharmaceutical company that has a direct connection with the research subject, nor from a company that provides or produces medical instruments and materials which may negatively affect the evaluation process of this study.

Conflict of Interest

No conflicts of interest between the authors and / or family members of the scientific and medical committee members or members of the potential conflicts of interest, counseling, expertise, working conditions, share holding and similar situations in any firm.
